ABSTRACT

We present transmission spectroscopy of the warm Saturn-mass exoplanet WASP-39b made with the *Very Large Telescope* (VLT) FOcal Reducer and Spectrograph (FORS2) across the wavelength range 411 – 810 nm. The transit depth is measured with a typical precision of 240 parts per million (ppm) in wavelength bins of 10 nm on a $V = 12.1$ magnitude star. We detect the sodium absorption feature ($3.2\text{-}\sigma$) and find evidence for potassium. The ground-based transmission spectrum is consistent with *Hubble Space Telescope* (HST) optical spectroscopy, strengthening the interpretation of WASP-39b having a largely clear atmosphere. Our results demonstrate the great potential of the recently upgraded FORS2 spectrograph for optical transmission spectroscopy, obtaining HST-quality light curves from the ground.

Keywords: planets and satellites: atmospheres – stars: individual – techniques: spectroscopic

1. INTRODUCTION

Transmission spectroscopy is a key to unlocking the secrets of close-in exoplanet atmospheres. Observations have started to unveil a vast diversity of irradiated giant planet atmospheres with clouds and hazes playing a definitive role across the entire mass and temperature regime (Charbonneau et al. 2002; Pont et al. 2008; Kreidberg et al. 2014; Knutson et al. 2014; Sing et al. 2016; Evans et al. 2016). Observations from space have played a leading role in the field, followed by significant achievements from the ground with the first results from multi-object (Bean et al. 2010; Gibson et al. 2013a; Crossfield et al. 2013; Jordán et al. 2013; Stevenson et al. 2014) and long-slit spectroscopy (Sing et al. 2012).

Ground-based spectrographs, operating at medium resolution have high potential for characterisation of transiting exoplanets, providing highly complementary optical transmission spectra to the near- and mid-IR regime, to be covered by the upcoming *James-Webb Space Telescope* (JWST). The FOcal Reducer and Spectrograph (FORS2, Appenzeller et al. 1998) mounted on the *Very Large Telescope* (VLT) at the European Southern Observatory (ESO) has recently undergone an upgrade, aiming an improvement of its capability for exoplanet transmission spectroscopy (Boffin et al. 2015).

Sedaghati et al. (2015) have recently presented observations of WASP-19b with the upgraded FORS2 instrument but found a featureless flat transmission spectrum.

We have initiated a ground-based, multi-object transmission spectroscopy of WASP-6b, WASP-31b and WASP-39b covering the wavelength range 360–850 nm using VLT FORS2. These targets were selected for follow-up as their transmission spectra showed evidence for alkali metal absorption, based on the results of *Hubble Space Telescope* (HST) observations (Nikolov et al. 2015; Sing et al. 2015; Fischer et al. 2016). Our aim is to test the performance of FORS2, following its recent recommissioning (Sedaghati et al. 2015), by comparing the transmission spectra against results from the HST.

In this paper we report the first results from our comparative study for WASP-39b. This warm Saturn is one of the most favourable exoplanets for transmission spectroscopy with a pressure scale height of $H > 1000$ km, translating to an atmospheric signal of $\Delta\delta = 455$ ppm (Winn 2010). The recent HST results of Sing et al. (2016) and Fischer et al. (2016) show agreement with model spectra of a clear atmosphere and evidence of absorption from sodium and potassium making WASP-39b an excellent target for ground-based optical transmission spectroscopy.

2. OBSERVATIONS

Time series observations were carried out during two primary transits of WASP-39b on UT 2016 March 8 and 12 with the FORS2 spectrograph mounted on the UT1 telescope at the European Southern Observatory on Cerro Paranal in Chile for program 096.C-0765 (PI: Nikolov). Data were collected in multi-object spectroscopy mode at medium resolution with a mask consisting of two broad slits centered on WASP-39 and one nearby reference star (known as 2MASS 14292245-0321010) at angular separation of ~ 5.7 arc minutes. The slits had lengths of ~ 90 arc seconds and widths of 22 arc seconds to eliminate possible differential slit light losses from guiding imperfections and seeing variations. Both observations were performed with the same slit mask and the red detector, which is a mosaic of two CCDs. The field of view was positioned such that each individual chip imaged the spectrum of one star. To improve the duty cycle the fastest available readout mode (~ 30 s) was employed.

During the first night we utilized the dispersive element GRIS600B, covering the spectral range from 360 to 620 nm at a resolving power of $R \sim 600$. We monitored WASP-39 and the reference star (B magnitude difference of -0.97) for 312 minutes under photometric conditions. The field of view rose from an air mass of 1.89 to 1.07 and set to an airmass of 1.16. The seeing gradually increased with median values from 0.7 to 1.8 arc seconds in the course of the observation, as measured from the spectra cross-dispersion profiles. A total of 216 exposures were collected with an integration time of 60 s.

During the second night we exploited the dispersive element GRIS600RI, covering the range from 540 to 820 nm in combination with GG435 filter to isolate the first order. Both sources (R magnitude difference of -1.26) were observed for 304 minutes under photometric sky conditions and increasing seeing with median value of 0.9 to 2.3 arc seconds. The field of view rose from an air mass of 1.53 to 1.07 and set to an air mass of 1.23. A telescope guiding error at UT 4:45 prevented data collection for ~ 5 min (during transit egress). A total of 232 exposures were collected with an integration time of 50 s.

3. DATA REDUCTIONS

Our analysis commenced from the raw images with subtraction of bias frame and flat field correction. The relevant master calibration frames were calculated by median-combining one-hundred individual frames. Spectral extractions were performed in IRAF employing the APALL procedure. The background was estimated by taking the median count level in a box of pixels away

from the spectral trace, and was subtracted from the stellar counts for each wavelength. We found the aperture diameters of 24 and 30 pixels and sky region from 40 to 70 pixels minimize the dispersion of the out of transit flux of the corresponding white light curves for the first and second night, respectively.

Wavelength calibration of the extracted stellar spectra was performed using spectra of an emission lamp obtained after each transit observation with a mask identical to the science mask, but with slit widths of 1 arc second. A wavelength solution was established for each source with a low-order Chebyshev polynomial fit to the centres of a dozen lines, the positions of which were determined with a Gaussian fit. We then placed the extracted spectra to a common Doppler corrected rest frame through cross-correlation to account for sub-pixel wavelength shifts in the dispersion direction. We found a displacement range of the spectra < 3 pixels during each observation with gravity flexure of the instrument being the most likely reason.

Example spectra of WASP-39 and the reference star are displayed in Figure 1. The typical signal-to-noise ratio (SNR) achieved for WASP-39 and the reference star were 267 and 160 per pixel for the central wavelength of GRIS600B and 326 and 191 per pixel for the central wavelength of GRIS600RI. The 1D spectra were then used to generate both white-light and spectrophotometric time series after summing the flux from each bandpass.

4. LIGHT CURVE ANALYSIS

White and spectroscopic light curves were created from the time series of each night for both the target and reference star by summing the flux of each stellar spectrum along the dispersion axis. Spectroscopic light curves were produced adopting the set of bands defined in Sing et al. (2016) to enable a direct comparison with the *HST* transmission spectrum of WASP-39b. White light curves were computed from 440 to 607 nm and from 540 to 810 nm for the first and second night, respectively. The range from 360 to 440 nm of GRIS600B was discarded in the subsequent analysis, due to insufficient SNR owing to low sensitivity of the red detector in that spectral region. Relative differential light curves were produced for the white and spectroscopic light curves by dividing the WASP-39 flux by the reference star flux. This correction removes the effects of atmospheric transparency variations as demonstrated in Figure 1. The light curve from the second night showed decrease of flux between ~ 30 min prior and ~ 80 after the mid-transit. The exact cause of this effect is unknown, but is likely related the vignetting of the field of view.

We fit each transit light curve with a two-component

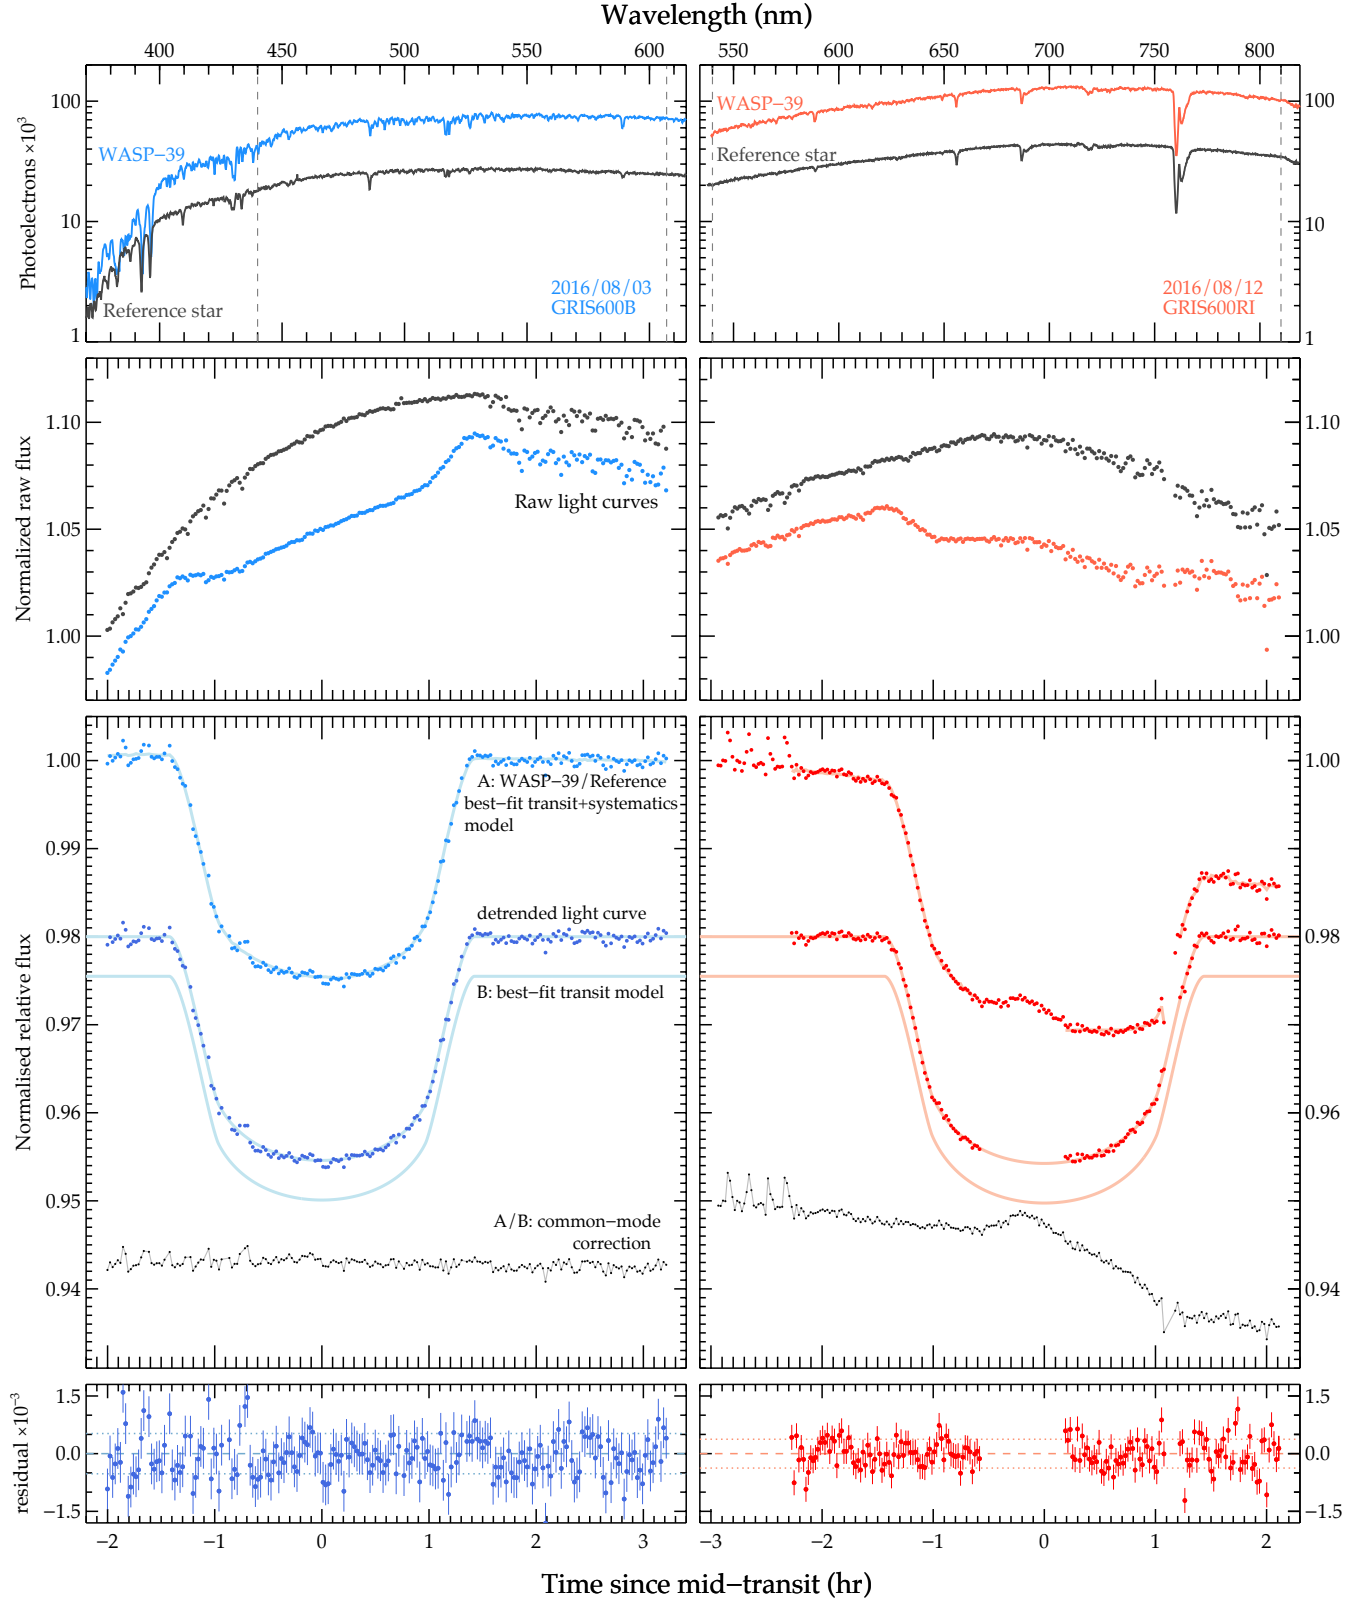

Figure 1. VLT FORS2 stellar spectra and the corresponding white transit light curves for WASP-39b and the reference star. Left and right column panels show the GRIS600B (blue) and GRIS600RI (red) datasets, respectively. *First row:* Example stellar spectra utilised for relative photometric calibration. The dashed line indicates the wavelength range used to produce the white light curves. *Second row:* Raw light curves of both sources. *Third row:* WASP-39 light curve relative to the reference star with the best-fit transit and systematics model (A), detrended light curve along with the best-fit transit model (B) and common-mode correction (A/B). *Fourth row:* Residual flux of the best-fit transit and systematics model to WASP-39.

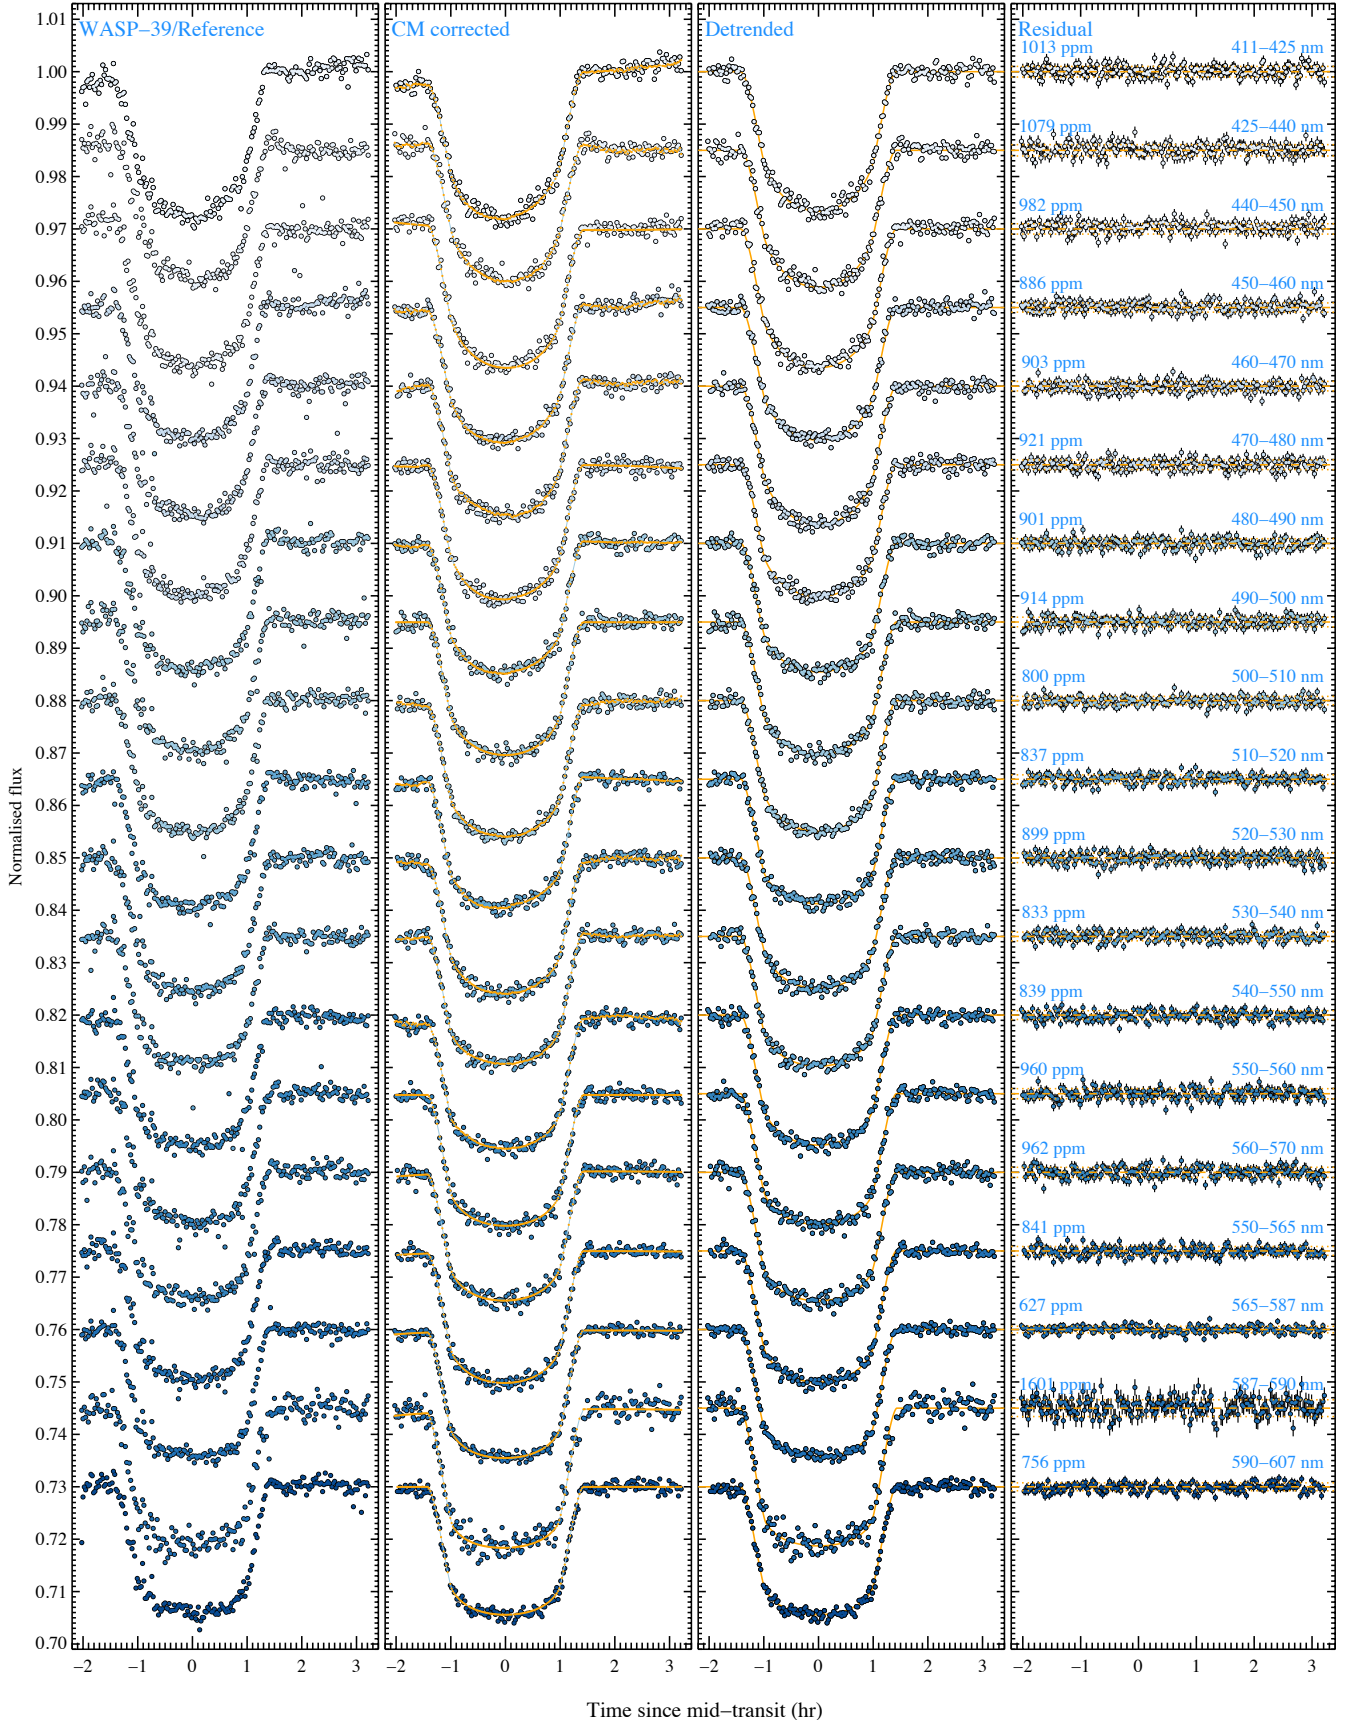

Figure 2. Spectroscopic light curves from GRIS600B offset by an arbitrary constant for clarity. *First panel:* raw target-to-reference flux. *Second panel:* common-mode corrected data and the best-fit model. *Third panel:* detrended light curves and the best-fit transit model. *Fourth panel:* residuals with 1σ error bars. The dashed lines show the median residual level with dotted lines indicating the dispersion, which is also labeled for each channel.

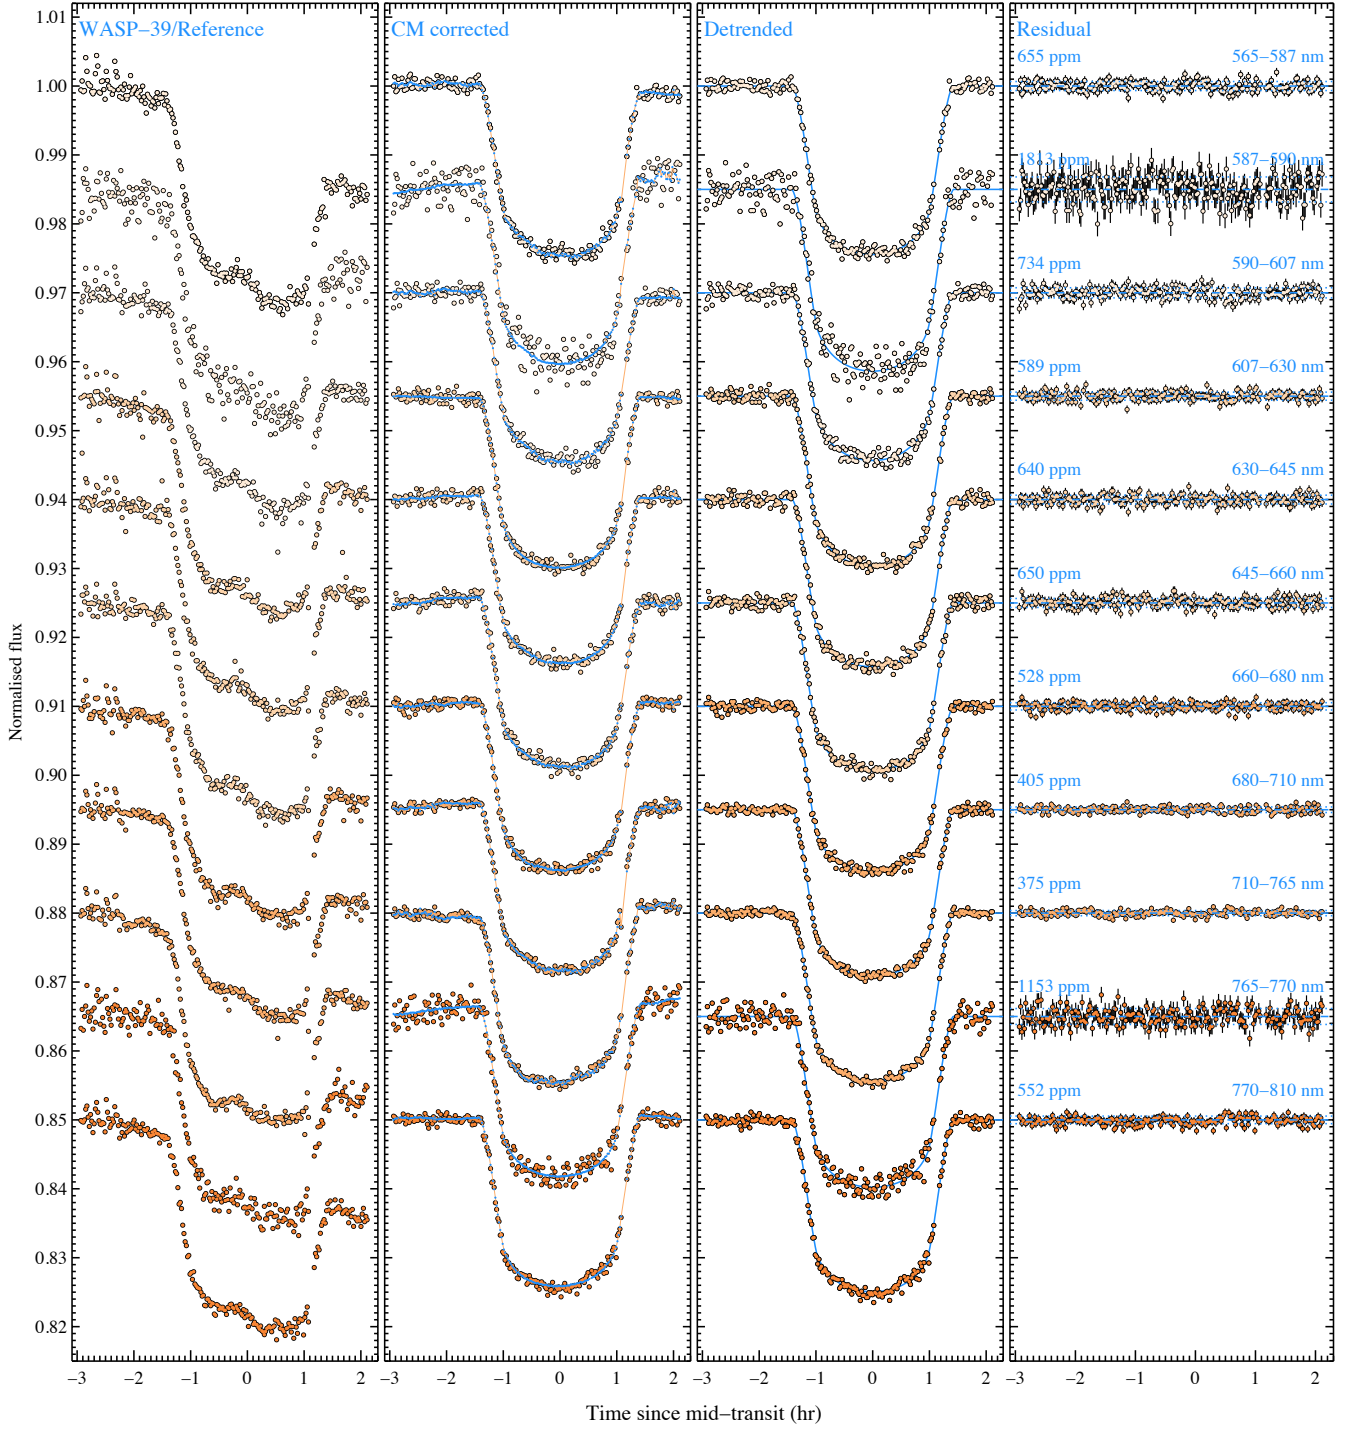

Figure 3. Same as Figure 2, but for GRIS600RI.

function that simultaneously models the transit and systematic effects. To model the transits, we adopted the complete analytic function given in [Mandel & Agol \(2002\)](#), which is parametrized with the mid-transit times (T_{mid}), orbital period (P) and inclination (i), normalized planet semimajor axis (a/R_*) and planet-to-star radius ratio (R_p/R_*).

Stellar limb-darkening was accounted for by adopt-

ing the two-parameter quadratic law of [Claret \(2000\)](#) with coefficients u_1 and u_2 , computed using 3D stellar atmosphere model grid ([Magic et al. 2015](#)), adopting the closest match to the effective temperature, surface gravity and metallicity of WASP-39 found in [Faedi et al. \(2011\)](#). Our choice for the limb-darkening law was motivated from the recent study of [Espinoza & Jordán \(2016\)](#), where the quadratic law has been demonstrated

to introduce a negligible bias on the derived transit parameters for transiting systems similar to WASP-39. The quadratic limb-darkening law has also been extensively used in previous multi-object spectroscopy characterization studies of transiting exoplanets, e.g. [Bean et al. \(2010\)](#); [Gibson et al. \(2013a,b\)](#); [Stevenson et al. \(2014, 2016\)](#); [Jordán et al. \(2013\)](#); [Mallonn et al. \(2015\)](#); [Mallonn & Strassmeier \(2016\)](#); [Nortmann et al. \(2016\)](#). Theoretical limb-darkening coefficients were obtained by fitting the limb-darkened intensities of the 3D models multiplied by the throughput profiles of GRIS600B and GRIS600RI ([Sing 2010](#)).

To account for systematics, we utilised a low-order polynomial (up to second degree with no cross terms) of air mass, spectral shift (displacement of the stellar spectra in the dispersion axis, as described in Section 3), average full-width-at-half-maximum (FWHM), the vertical position of the centre of the spectrum of each channel, time and the rate of change of the rotator angle. We then generated systematics models spanning all possible combinations of detrending variables and performed separate fits using each systematics model included in the two-component function. The Akaike information criterion (AIC; [Akaike 1974](#)) was calculated for each attempted function and used to marginalize over the entire set of functions following [Gibson \(2014\)](#). Our choice to rely on the AIC instead of the Bayesian information criterion (BIC; [Schwarz 1978](#)) was determined by the fact that the BIC is more biased towards simple models than the AIC. The AIC therefore provides a more conservative model for the systematics and typically results in larger/more conservative error estimates as demonstrated by [Gibson \(2014\)](#). Marginalization over multiple systematics models assumes equal prior weights for each model tested. This is a sensible assumption for simple polynomial expansions of basis inputs; however, the introduction of more complex functional forms of the inputs (e.g. exponentials, sinusoids) would break the symmetry of the models and weaken this assumption when using simple model selection criteria such as the AIC.

The errors on each spectrophotometric data points from each time series were initially set to the pipeline values, which are dominated by photon noise with readout noise also taken into account. We determine the best-fitting parameters simultaneously with the Levenberg–Marquardt least-squares algorithm as implemented in the MPFIT¹ package [Markwardt \(2009\)](#) using the unbinned data. The final results for the uncertainties of the fitted parameters were taken from MPFIT

after we rescaled the errors per data point based on the standard deviation of the residuals. Residual outliers larger than 3σ (typically a few) were clipped in all light curves and the final results obtained with a fit performed using the rest of the data.

Table 1. System parameters

Parameter	Value
P (day)	4.055259 (adopted)

T_{mid} (MJD)	57459.32103 ± 0.00021
i , ($^\circ$)	88.07 ± 0.23
a/R_*	11.64 ± 0.15
R_p/R_*	0.1457 ± 0.0013
u_1	0.485 ± 0.065
u_2	0.30
<i>Weighted mean:</i>	
i , ($^\circ$)	87.79 ± 0.14
a/R_*	11.54 ± 0.11
R_p/R_* , GRIS600B	0.14696 ± 0.00062
R_p/R_* , GRIS600RI	0.14600 ± 0.00084

When fitting the white light curve from the second night we excluded data points from the first ~ 40 minutes (due to higher noise) and those exhibiting the flux drop as detailed in Section 3. We modelled each of the three remaining pieces of the light curve with individual systematics models and common transit model. We found an excellent agreement between the fitted transit parameters from the two nights (Table 1).

For the spectroscopic light curves, a common-mode systematics model was established by simply dividing the white transit light curve to a transit model ([Sing et al. 2012](#); [Deming et al. 2013](#); [Gibson et al. 2013a,b](#); [Huitson et al. 2013](#); [Nikolov et al. 2015](#)). We computed the transit model using the weighted mean values of the orbital inclination and a/R_* from both observations. To find the best-fit radius and limb-darkening coefficients for the white light curves, we fitted for those quantities but fixed the remaining parameters to the weighted

Figure 4. Comparison between the WASP-39b transmission spectrum from *VLT* FORS2 and *HST* STIS. The top panel displays the individual measurements with their uncertainties. The lower panels display the radius differences, assuming the uncertainty of the FORS2 and STIS measurements. The residual distribution is shown on the right along with the best-fit gaussian indicated with the red continuous line.

mean values and the measured white light transit depths are reported in Table 1.

We found systematics models containing an air mass, spectral shift and FWHM terms to result in the highest evidence for the white light curves. Following Pont et al. (2006), we assessed the levels of residual red noise by modelling the binned variance with a $\sigma^2 = (\sigma_w)^2/N + (\sigma_r)^2$ relation, where σ_w is the uncorrelated white noise component, N is the number points in the bin, and σ_r characterises the red noise. Typical white and red noise dispersions were found to be $\sigma_w \sim 540$ and ~ 410 and $\sigma_r \sim 105$ and ~ 100 ppm. The weighted mean values and radii found in the white light curve analysis are in excellent agreement with the results of Sing et al. (2016) and Fischer et al. (2016).

The common-mode technique relies on the similarities of time dependent systematics, which can be characterised by the light curves themselves and removed individually for each spectral wavelength bin. Empirically determining and removing slit light losses has an advantage over a parameterised method, as higher order frequencies are naturally subtracted. The common-mode factors from each night were then removed from the corresponding spectroscopic light curves prior to model fitting (see Figure 1).

We then performed fits to the spectroscopic light

curves using the same set of systematics models as in the white light curve analysis and marginalised over them as described above. For these fits, R_p/R_* and the first limb-darkening coefficient u_1 were allowed to vary for each spectroscopic channel, while the central transit time and system parameters were fixed to the weighted mean values. Again, the same quadratic limb-darkening law was used with the non-linear coefficient fixed to its theoretical value, determined in the same way as for the white light curve and u_1 allowed to vary. We performed tests by fitting only the first or second coefficient and fixing the other to its theoretical value finding no difference in the resulting transmission spectrum. Fitting for the linear limb-darkening coefficient is a practice introduced by Southworth (2008), which has been demonstrated to generally perform well. Ground-based multi-object spectroscopy studies have also implemented this methodology, e.g. Stevenson et al. (2014, 2016); Mallonn et al. (2015); Mallonn & Strassmeier (2016). We also fitted for both limb-darkening coefficients simultaneously and found that the uncertainty of the non-linear coefficient is large. This implies that the quality of the light curves is insufficient for constraining the non-linear coefficient. However, since the transmission spectrum did not significantly change we choose to fix the non-linear term to its theoretical prescription and fit for the

linear term only. We report the results for R_p/R_* and the limb-darkening parameters in Table 2 and show the best-fit transit models in Figure 2 and 3. Much simpler systematics models were favoured at the marginalization step for the spectroscopic light curves, typically containing only one term, e.g. linear airmass or a spectral shift term. In addition, we found that the spectroscopic light curves showed less scatter when flat fielding was not applied.

Table 2. Transmission Spectrum and Quadratic Limb-darkening Coefficients

λ , nm	R_p/R_*	u_1	u_2
411 – 425	0.14673 ± 0.00255	0.612 ± 0.027	0.216

565 – 587	0.14479 ± 0.00114	0.348 ± 0.015	0.310
587 – 590	0.14951 ± 0.00214	0.352 ± 0.038	0.311
590 – 607	0.14389 ± 0.00130	0.385 ± 0.017	0.312
607 – 630	0.14516 ± 0.00070	0.351 ± 0.013	0.313
630 – 645	0.14440 ± 0.00088	0.331 ± 0.015	0.314
645 – 660	0.14520 ± 0.00113	0.329 ± 0.016	0.313
660 – 680	0.14446 ± 0.00120	0.324 ± 0.012	0.314
680 – 710	0.14414 ± 0.00067	0.327 ± 0.010	0.314
710 – 765	0.14459 ± 0.00145	0.323 ± 0.012	0.315
765 – 770	0.14742 ± 0.00130	0.300 ± 0.026	0.315
770 – 810	0.14643 ± 0.00090	0.309 ± 0.013	0.315

As checks of our reduction methods, we also performed a fit to the spectroscopic light curves without a common-mode correction and inflated the uncertainties with the β scaling parameter. We also measured the radii for the

blue grism treating the systematics as a time-dependent Gaussian process (Gibson et al. 2012) without applying the common-mode correction, finding a consistent transmission spectrum. For the red grism the systematics are more complex and cannot be modelling using only time-dependence. In all those checks we found the final transmission spectra in excellent agreement.

5. TRANSMISSION SPECTRUM

The measured *VLT* FORS2 transmission spectrum of WASP-39b is plotted in Figure 4. Its main characteristics include a sodium and potassium absorption features, spanning ~ 5 and ~ 3 atmospheric pressure scale heights, respectively and a relatively flat baseline. Band 587-590 nm, centered on the sodium line core shows larger absorption than the surrounding bands in each of the two separate epoch observations with GRIS600B and GRIS600RI. Comparing the pairs of radius measurements of our result to the spectrum of (Sing et al. 2016), one can find that all of the measurements are in agreement within their uncertainties. A least squares fit with a constant being the only fitted parameter to the differences between the *HST* STIS and *VLT* FORS2 spectra, using the uncertainties combined in quadrature, gives χ^2 of 38.68 for 27 degrees of freedom and an offset between both spectra $\Delta R_p/R_* = 0.00097 \pm 0.00043$. The probability of obtaining that value of χ^2 is $\sim 7\%$ and cannot reject a constant offset model, implying that the spectra are consistent. It should be noted that the overall level of the *VLT* FORS2 transmission spectrum is as uncertain as the white light curve depths for both grisms (see Section 4), which accounts for common-mode corrections, and correlations with other transit parameters that are fixed for the spectroscopic fits. When stitching together multiple transit spectra one can ensure the same system parameters are used, but cannot correct for bias in various common-mode corrections.

To estimate the significance of Na and K detection we performed a horizontal line fit to the FORS2 transmission spectrum, excluding the measurements in the Na (2) and K (1) bins. We then computed the weighted mean value of the Na measurement and compared the difference of that measurement with the one from the horizontal line. Doing so for the Na and K lines we found 3.2 and 1.7 σ confidence levels.

6. DISCUSSION

We compared the FORS2 transmission spectrum to a variety of different cloud-free atmospheric models based on the formalism of Fortney et al. (2008, 2010). We averaged the models within the transmission spectrum wavelength bins and fitted these theoretical values to the data with a single free parameter that controls their vertical position. We computed the χ^2 statistic to quantify

Figure 5. Comparison of the FORS2 transmission spectrum (dots and boxes refer to GRIS600B and GRIS600RI, respectively) to models (continuous lines).

model selection with the number of degrees of freedom for each model given by $\nu = N - m$, where N is the number of data points and m is the number of fitted parameters.

Results from the model comparison are shown in Figure 5. We find the cloud-free solar-metallicity models with an artificially added $1\times$ uniform absorber from large particles (red line) and $10\times$ Rayleigh scattering from small particles (blue line) to be the best-match to the 28 data points. The featureless models with $100\times$ enhanced scattering from large particles (the horizontal brown line in Figure 5) and $1000\times$ Rayleigh scattering (orange line) resulted in quite high values for the χ^2 -statistic and were disfavoured.

We also performed a linear fit to the Rayleigh slope from 400 to 530 nm to empirically measure the temperature at the planet’s day-night terminator. Assuming an atmospheric opacity source(s) with an effective extinction (scattering+absorption) cross-section that follows a power law of index α , i.e. $\sigma = \sigma_0(\lambda/\lambda_0)^\alpha$, the transmission spectrum is then proportional to the product αT given by

$$\alpha T = \frac{\mu g}{k} \frac{d(R_p/R_*)}{d \ln \lambda}. \quad (1)$$

where μ is the mean molecular mass, g is the surface gravity, k is the Boltzman constant and T is temperature (Lecavelier Des Etangs et al. 2008). We found a good fit to the 12 FORS2 data points ($\chi^2 = 3.1$ for $\nu = 10$, $m = 2$) giving $\alpha T = -4795 \pm 3913$ K. For comparison a horizontal line fit (cloud deck) resulted in slightly worse fit with $\chi^2 = 3.9$ for $\nu = 11$, $m = 1$. Adopting the equilibrium temperature from Faedi et al. (2011), the slope of the transmission suggests an effective extinction cross-section of $\sigma = \sigma_0(\lambda/\lambda_0)^{-4.3 \pm 3.5}$, which is consistent with Rayleigh scattering.

When assuming Rayleigh scattering (i.e. adopting $\alpha = -4$), which is the case for a pure gaseous H_2 atmosphere or scattering we find a best-fit terminator temperature of 1199 ± 978 , which is in agreement with the result of Fischer et al. (2016).

The model comparison to our *VLT* observations demonstrate that scenarios including an atmosphere dominated by a cloud deck or strong Rayleigh scattering are ruled out. A clear atmosphere with presence of clouds and hazes seem to be the most plausible scenario for WASP-39b, which is in agreement with the results from *HST* and *Spitzer*. This is in contrast to WASP-6b and HD 189733b, two other planets with equilibrium

temperatures similar to WASP-39b (~ 1100 K) and measured optical transmission spectra revealing hazy atmospheres.

Our results also demonstrate the capability and high potential of FORS2 to characterise exoplanets in transmission. We note that the efficiency and wavelength coverage of our observation could further be increased by exploiting the blue rather than the red detector when utilising grism GRIS600B with an expected improvement of $\sim 2\times$ in SNR. This is especially pertinent to constraining the near-UV slope caused by molecular hydrogen and could provide constraints on the planet temperature and base pressure.

7. CONCLUSION

We report on a ground-based optical transmission spectrum for WASP-39b covering the wavelength range from 411 to 810 nm obtained with the recently upgraded *VLT* FORS2 instrument, configured for multi-object spectroscopy. We detect an absorption from sodium ($\sim 3.2\sigma$) and find evidence of potassium ($\sim 1.7\sigma$). Our spectrum is consistent with the transmission spectrum obtained with the *HST* and further reinforces the find-

ing of largely clear atmosphere. Our study demonstrates the large potential of the instrument for optical transmission spectroscopy, capable of obtaining *HST*-quality light curves from the ground. Compared to *HST*, the larger aperture of *VLT* will allow for fainter targets to be observed and higher spectral resolution, which can greatly aid comparative exoplanet studies.

Based on observations collected at the European Organisation for Astronomical Research in the Southern Hemisphere under ESO programme 096.C-0765(E). We are grateful to the anonymous Referee for their valuable comments and suggestions for improving the manuscript. The research leading to these results received funding from the European Research Council under the European Union Seventh Framework Program (FP7/2007-2013) ERC grant agreement no. 336792. N.P.G. gratefully acknowledges support from the Royal Society in the form of a University Research Fellowship. J. K. B. ERC acknowledges support from project 617119 (ExoLights). P.A.W acknowledges the support of the French Agence Nationale de la Recherche (ANR), under program ANR-12-BS05-0012 "Exo-Atmos".
